Sinusitis (Sinus Infection) in Children —
Definition and Symptoms

Acute sinusitis is very common in children and can be classified as bacterial or viral depending on the etiology. The diagnosis of acute sinusitis in children should be based on the presence of clinical findings that are suggestive of acute sinusitis rather than on imaging findings. The diagnosis can be confirmed by performing a culture and sensitivity test of the paranasal discharge. Once the diagnosis of acute bacterial rhinosinusitis is suspected, antibiotic therapy should be initiated. Symptomatic treatment of viral sinusitis includes oral antihistamines and topical decongestants. Adjunctive therapy for bacterial sinusitis includes intranasal corticosteroids.

Overview

Acute sinusitis in children can be defined as the acute inflammation of the mucosa of the paranasal sinuses or the nasal passages with a duration less than 4 weeks. This inflammatory condition can be caused by viral infections, bacteria or fungi. Non-infectious etiologies of acute sinusitis can be allergies or irritants.
Epidemiology of Sinusitis in Children

Upper respiratory tract infections are very common in children with an estimated incidence of 6 episodes per patient-year. Approximately, 8% of these upper respiratory tract infection episodes are complicated by rhinosinusitis in children aged between 6 and 35 months of age.

There are no differences in the incidence of rhinosinusitis among boys and girls but the condition is becoming more common in both sexes within the last decade.

Children who are born with genetic disorders that impair mucosal ciliary movement or who have impaired secretory immune response are predisposed to recurrent rhinosinusitis episodes.

Etiology and Pathophysiology of Sinusitis

The most common etiology of rhinosinusitis in children is viral in origin. Secondary bacterial infections of the sinuses are a common complication in children. Streptococcus pneumoniae, Moraxella catarrhalis, staphylococcus aureus and nontypeable Haemophilus influenzae are the most commonly identified bacterial etiologies of bacterial rhinosinusitis in children.

For bacteria to colonize the nasal and paranasal sinuses and cause symptoms in children, certain pathological changes must happen first within the nasal and paranasal passages.

The most important pathophysiological change encountered is the obstruction of the sinus drainage pathways. A common cause of obstructed sinus drainage pathways in children is otitis media.

Additionally, children with recurrent bacterial rhinosinusitis usually have some evidence of ciliary impairment and altered mucus quantity or quality. The most common causes of altered mucus quantity and quality in children include asthma and other allergic conditions.

Viral upper respiratory tract infections can also alter the composition and quantity of the mucus within the nasal and paranasal sinuses which can put the child at an increased risk of acquiring a secondary bacterial infection.

Clinical Presentation of Sinusitis in Children

When a child presents with symptoms and signs suggestive of an upper respiratory tract infection, one should pay attention to the severity of the symptoms and the possibility of the presence of a complicating rhinosinusitis.

Almost all children with viral upper respiratory tract infections have rhinosinusitis, therefore, we will focus on differentiating bacterial from viral sinusitis. This distinction is important because viral rhinosinusitis resolves spontaneously while bacterial rhinosinusitis in children requires specific antimicrobial therapy.

The diagnosis of acute bacterial sinusitis is made when the child has two major criteria or one major criteria and two or more minor criteria from the clinical diagnostic criteria of bacterial sinusitis in children.

The major criteria include the presence of facial pain, facial congestion, nasal
congestion, nasal discharge which can be purulent, loss of the sense of smell, the presence of purulent discharge on intranasal examination and finally the presence of fever. The minor criteria for the diagnosis of acute bacterial sinusitis in children include the presence of headache, halitosis, fatigue, dental pain, cough and ear pain.

Once the diagnosis of acute sinusitis is suspected in a child, the treating physician should look for any clues that point towards a possible bacterial etiology rather than a viral one. The most crucial differences between bacterial and viral acute sinusitis in children in favor of bacterial sinusitis are a duration of respiratory symptoms of more than 10 days, the presence of purulent nasal discharge and a high-grade fever, and worsening of the symptoms after an initial temporary improvement.

Another important distinction to be made during the clinical examination and history taking is between non-severe and severe bacterial sinusitis.

Children with severe sinusitis usually have purulent thick nasal discharge, more severe facial pain and headache, might have periorbital edema and have a high-grade fever. Children with non-severe bacterial sinusitis usually have rhinorrhea, nasal congestion, cough, less-severe facial pain, and low-grade fever or no fever.

Diagnostic Workup for Sinusitis in Children

Proper history taking and physical examination is required in a child who presents with upper respiratory tract infection symptoms to differentiate between viral and bacterial etiologies. Patients with suspected acute bacterial sinusitis should be offered advanced confirmatory tests whenever possible before starting antibiotic therapy.

Laboratory investigations are usually not helpful in children with acute sinusitis as leukocytosis is rarely seen. Children with severe acute bacterial rhinosinusitis who are ill and toxic might have leukocytosis and neutrophilia.

The best diagnostic test to confirm the diagnosis of bacterial sinusitis in children is a culture and sensitivity test from the paranasal sinus cavity. The presence of more than 10⁴ colony-forming units/mL on bacterial culture is confirmatory of bacterial sinusitis in children.

Sinus aspiration is rarely used in children because it is considered as too invasive, painful and impractical. Endoscopic-guided middle meatus cultures can provide sinus aspirates to confirm the diagnosis of acute bacterial rhinosinusitis but their validity has not been tested in children.

Imaging studies can provide more clues towards the diagnosis of acute sinusitis in children but they have several drawbacks. First, computed tomography studies might show sinus abnormalities even in healthy children. Second, skull x-rays and computed tomography scans cannot differentiate between viral and bacterial sinusitis. Third, imaging studies of the sinuses in children with viral upper respiratory tract infections can show sinus abnormalities in more than 80% of the cases without any clinical symptoms and signs suggestive of sinusitis.

Because of these reasons, imaging studies in children should be reserved only for complicated and recurrent cases.

Imaging studies are more useful in excluding the diagnosis of acute sinusitis rather than confirming it. A negative computed tomography scan is very reliable in
excluding acute sinusitis as the cause behind headache and facial pain in a child. Magnetic resonance imaging studies of the brain are useful in excluding complications of acute bacterial sinusitis such as brain abscess and cerebrovascular venous thrombosis.

**Treatment of Sinusitis in Children**

Once the diagnosis of acute bacterial rhinosinusitis in a child is made, **empirical antibiotic therapy** should be started. Additionally, **symptomatic treatment of nasal and sinus congestion** is indicated to decrease the severity and duration of the symptoms.

The antibiotic of choice for acute bacterial sinusitis in children is **amoxicillin-clavulanate**. The dosage of amoxicillin-clavulanate is usually dependent on the severity of the bacterial sinusitis.

Children with non-severe sinusitis usually receive a standard dose defined as 45 mg/kg/d orally 3 times a day. High-dose amoxicillin-clavulanate is defined as 90 mg/kg/d orally twice a day and should be reserved for children with severe bacterial sinusitis.

If the diagnosis of **penicillin-resistant streptococcus pneumoniae** sinusitis is suspected, the child can receive cefixime plus clindamycin instead of amoxicillin-clavulanate.

Children with immediate-type **hypersensitivity reaction to penicillin** should receive levofoxacin instead of amoxicillin-clavulanate. Children with delayed hypersensitivity reaction to penicillin can receive cefixime plus clindamycin for the treatment of acute bacterial sinusitis regardless of the penicillin-resistance status within the bacterial isolate.

In contrast to adults, short-term antibiotic therapy is not recommended in children. Instead, 10 days up to two weeks of empirical antibiotic therapy is recommended. Children usually show significant improvement of their symptoms within 5 days from the initiation of antibiotic therapy.

**Topical decongestants** and **oral antihistamines** should be avoided in children with acute bacterial rhinosinusitis. Children who are more likely to have viral rhinosinusitis however should receive topical decongestants or oral antihistamines because these agents are proven to provide symptomatic relief in this group of patients.

**Adequate hydration** and **mucolytic agents** might be useful in children with acute bacterial rhinosinusitis as they facilitate sinus drainage and can achieve symptomatic relief. On the other hand, **intranasal corticosteroids** have showed objective clinical improvement in children with acute bacterial sinusitis and are recommended as an adjunctive therapy.

Children who fail to respond to medical therapy or who have too often recurrences should be offered **surgical drainage** of their sinuses. **Functional endoscopic sinus surgery** is the best therapeutic option and has been shown to achieve success in about 75% of the cases of complicated, persistent bacterial sinusitis.
